```
head []

printf "blah %s %s" "hello"

-- *** Exception: printf: argument list ended

-- prematurely
```

There are two main reasons that this happens

There are two main reasons that this happens

- Most functional languages have two languages that can't interact: the Type language, and the programming language
 - Types exist only as an enforcement layer
- Since these languages can't interact, all the types and conditions for them must be known by the programmer ahead of time, and can't can't be deduced from the context of the code.

The solution to these problems (and many others) are dependent types $\,$

A dependently typed language generally means two things:

• Types, like functions, are first-class citizens that can be built dynamically (without it being dynamic typing)

Functions can be called inside the type signature, all at compile-time.

Lists are annoying for a couple reasons

```
head []
-- *** Exception: Prelude.head: empty list
zipWith (\i j -> i + j) [1,2,3,4] [1]
--- [2]

• Even getting the length requires O(n) operations.

```

- Even getting the length requires O(n) operations.
 - You could store the length as a property, but that requires anyone who updates length to make sure it's updated
 - Generally ok for well-audited things, risky for anything else.

Let's code it!

Variadic functions (in most languages) are convenient, but terrible.

- Compiler can't check to see if you have the correct number of arguments

More coding!

A note about compiler hacks

F#'s printfn works as you would expect due to a special case in the compiler doing static analysis on that particular case.

This is totes OK, but that only works for that particular case.

I don't expect everyone here to convert all their stuff to Idris, so why am I talking?

- Because dependent types are super cool, and worth a ton of further research.
